Abstract. We propose a new global SPACING constraint that is useful in modeling events that are distributed over time, like learning units scheduled over a study program or repeated patterns in music compositions. First, we investigate theoretical properties of the constraint and identify tractable special cases. We propose efficient *DC* filtering algorithms for these cases. Then, we experimentally evaluate performance of the proposed algorithms on a music composition problem and demonstrate that our filtering algorithms outperform the state-of-the-art approach for solving this problem.

1 Introduction

When studying a new topic, it is often better to spread the learning over a long period of time and to revise topics repeatedly. This "spacing effect" was first identified by Hermann Ebbinghaus in 1885 [1]. It has subsequently become "one of the most studied phenomena in the 100-year history of learning research" [2]. It has been observed across domains (e.g. learning mathematical concepts or a foreign language, as well as learning a motor skill), across species (e.g. in pigeons, rats and humans), across age groups and individuals, and across timescales (e.g. from seconds to months). To enable learning software to exploit this effect, Novikoff, Kleinberg and Strogratz have proposed a simple mathematical model [3]. They consider learning a sequence of educational units, and model the spacing effect with a constraint defined by two sequences, $A = [a_1, a_2, \ldots]$ and $B = [b_1, b_2, \ldots]$. For each unit being taught, the $i + 1$st time that it should be reviewed is between a_i and b_i time steps after the ith time.

This technical report, after giving a brief background in the following section, describes and analyses the Global SPACING Constraint in the section 3. Then the sections 4, 5, 6, 7 and 8 explore restrictions of the constraint and identify tractable special cases. In the sections 5 and 6 we propose efficient filtering algorithms for these tractable cases. In the section 9, we describe a useful application of the constraint to solving a music composition problem. The section 10 presents experimental evaluation of the SPACING constraint on the music composition problems.

2 Background

2.1 Constraint Satisfaction Problems (CSP)

A constraint satisfaction problem consists of a set of variables, each with a finite domain of values, and a set of constraints specifying allowed combinations of values for subsets of variables. We use capital letters for variables (e.g. X and Y), and lower case for values (e.g. d and d'). We write $D(X)$ for the domain of a variable X and $D = \bigcup_{i=1}^{n} D(X_i)$ for the set of all the domain values. Assigning a value $d \in D(X)$ to a variable X means removing all the other values from its domain. A solution is an assignment of values to the variables satisfying the constraints. Constraint solvers typically explore partial assignments enforcing a local consistency property using either specialized or general purpose propagation (or filtering) algorithms. A *support* for a constraint C is an assignment that assigns to each variable some value from its domain and satisfies C. A constraint is *domain consistent* (*DC*) iff for each variable X_i, every value in $D(X_i)$ belongs to some support.

2.2 Matching Theory

We also give some background on matching. A *bipartite graph* is a graph $G = (U, V, E)$ with the set of nodes partitioned between U and V such that there is no edge between two nodes in the same partition. A *matching* in a graph G is a subset of E where no two edges have a node in common. A *maximum matching* is a matching of maximum cardinality. Regin[4] proposed efficient propagator based on a maximum matching algorithm.

2.3 Propositional Satisfiability (SAT)

A *Propositional Satisfiability* (SAT) is a problem of finding a model of a propositional formula. The propositional formula is usually in *Conjunctive Normal Form* (CNF), which is a set of clauses. We consider the clauses to be sets of literals. A literal is either a propositional variable (i.e. p) or a negated propositional variable (i.e. $\neg p$). The set of all variables from ϕ is $var(\phi)$ and $\neg var(\phi) = \{\neg p \mid p \in var(\phi)\}$. Without loss of generality we can order the variables from $var(\phi)$ into sequence $[p_1, \ldots, p_v]$ and the clauses of ϕ into sequence $[C_1, \ldots, C_c]$. Let $lit(\phi) = var(\phi) \cup \neg var(\phi)$. Then a set of literals $I \subseteq lit(\phi)$ is an interpretation of ϕ if it is maximal and consistent, i.e. it does not contain a pair of complementary literals $l \in I \rightarrow \overline{l} \notin I$. An interpretation I of ϕ is a model of ϕ if it contains at least one literal from each clause of ϕ. We also use the following notation: if L is a set of literals, then $L' = \{l' \mid l \in L\}$ and $L^i = \{l^i \mid l \in L\}$.

3 The Global SPACING Constraint

First we describe the Global SPACING Constraint and then its further restrictions in the following sections. For simplicity, we introduce a function that returns the number of occurrences of a domain value $d \in D$ in a sequence of variables $X = [X_1, \ldots, X_n]$. It is $occ(d, X) = |\{i \mid X_i = d, 1 \leq i \leq n\}|$ Now we define the Global SPACING Constraint as follows:

Definition 1. *Let $X = [X_1, \ldots, X_n]$ be a sequence of n variables and let $S \subseteq D$ be a set of domain values. Let $A = [a_1, \ldots, a_{k-1}]$ and $B = [b_1, \ldots, b_{k-1}]$ be sequences of natural numbers such that $a_i \leq b_i$ for $1 \leq i \leq k-1$. Then* SPACING(S, A, B, X) *holds iff for all i s.t. $1 \leq i \leq k-1$ and for all $d \in S$ it holds that if there exists j s.t. $1 \leq j \leq n$ and $X_j = d$ and $occ(d, [X_1, \ldots, X_j]) = i$ then there exists $j' \leq n$ s.t. $j + a_i \leq j' \leq j + b_i$ and $X_{j'} = d$ and $occ(d, [X_1, \ldots, X_{j'}]) = i + 1$.*

In other words, each value $d \in S$ either does not occur in X at all, or it occurs on at least k different places and the distances between the places are determined by the sequences A and B. The *minimum distance condition* forces the $i+1$st occurrence of the value d to be no closer than a_i places from its ith occurrence and the *maximum distance condition* forces the $i+1$st occurrence to be no further than b_i places from the ith occurrence.

For example, suppose we need to prepare a playlist for a radio station. The SPACING Constraint allows us to specify that any of top ten songs is either not played at all, or it is played at least four times in the 360 song long playlist and it is not repeated more frequently than every 30 songs, but at least every 90 songs. The constraint would be imposed on the sequence $X = [X_1, \ldots, X_{360}]$ of $n = 360$ variables. The domain values would represent the songs and $S \subseteq D$ would be the set of the top ten songs. The number of spaced occurrences is $k = 4$, so the sequences A and B would be of length $k-1 = 3$. Overall the constraint would be specified as SPACING$(S, [30, 30, 30], [90, 90, 90], X)$.

Theorem 1. *Enforcing* DC *on the Global* SPACING *Constraint is NP-hard.*

Proof. We prove this by reduction of SAT to the problem of finding a support for SPACING. Let ϕ be an arbitrary CNF with v propositional variables and c clauses. We will abuse the notation slightly by using literals as domain values. There is a model of ϕ iff there is a support for the constraint SPACING$(S, [a_1, \ldots, a_{k-1}], [b_1, \ldots, b_{k-1}], X)$ with

- $S = lit(\phi)$
- $k = c + 1$
- $a_i = 1$ and $b_i = v + 1$ for $1 \leq i \leq k-1$
- X is a sequence of $vc + v + c$ variables with domains as described below.

If we cut the sequence X into slices $v+1$ variables long and put the slices under each other, we obtain a table with $c+1$ rows where the last cell is empty. For simplicity the variables will be indexed $X_{j,i}$, where j is a row number and i is a column number, i.e. $X_{j,i}$ stands for $X_{(j-1)(v+1)+i}$. The first v columns will represent the propositional variables of ϕ, so

- the domains of variables $X_{j,i}$ for $1 \leq i \leq v$ and $1 \leq j \leq c+1$ are $\{p_i, \neg p_i\}$.

The last column represents ϕ, each clause in one row, so the domains are sets of literals from particular clauses. Simply,

- the domains of variables $X_{j,v+1}$ for $1 \leq j \leq c$ are C_j.

For example take CNF $\phi = [\{\neg p, q, r\}, \{\neg q, r\}, \{\neg p, \neg q\}, \{p, q\}]$ the equivalent constraint would be SPACING$(S, [1, 1, 1, 1], [4, 4, 4, 4], X)$ with $S = \{p, q, r, \neg p, \neg q, \neg r\}$ and X would contain 19 variables with domains ordered into the following table:

$i =$	1	2	3	4
$j = 1$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{\neg p, q, r\}$
$j = 2$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{\neg q, r\}$
$j = 3$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{\neg p, \neg q\}$
$j = 4$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{p, q\}$
$j = 5$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	

Note that $D \subseteq S$. So if a value occurs in a support for the constraint, it has to occur in it at least $c + 1$ times. Due to construction of the domains, one value can occur on at most $2c + 1$ places (in one of the first v columns and in the last column). Each value is sharing $c + 1$ of these places with its complement, thus if a value occurs in a support, it occupies at least $c + 1$ of $2c + 1$ places, so its complement does not have space to repeat enough times to satisfy the constraint. Hence if a value occurs in a support it will occupy one of the first v columns completely, because its complement cannot.

Consequently, if we have a support for the constraint, the set of values assigned to the first v variables is a model of ϕ, because each value selected in the last column has to occur in it and complement of none of these values can occur in it.

On the other hand, if we have a model of ϕ, we can obtain a support for the constraint by assigning the literals from the model to all the variables as a values. This is always possible, because a model interprets all the literals and it is consistent, so there will be exactly one value for each of the variables in the first v columns, and a model satisfies each clause, so there will be some value for each variable in the last column. This will really be a support for the constraint, because each value that will occur in it will occur in each row at least once. □

Please, note that the proof does not make use of the condition of minimal spacing imposed by the sequence A. Also the sequence B is constant ($b_i = b_{i+1}$ for all $1 \leq i \leq k - 2$), so the proof holds also for much simpler constraint. In fact, the proof does not use the condition that the values have to be repeated, it is based barely on the number of occurrences. The reason why SPACING is NP-hard is that there is a possibility for the values to either occur in the support or not. Next we will examine a case that does not provide such a possibility.

4 The Forced Global SPACING Constraint (SPACING$_F$)

This section describes a restriction of the constraint where all the values from S are forced to occur in the sequence and later it analyses also restriction with the distance conditions relaxed.

Definition 2. *Let $X = [X_1, \ldots, X_n]$ be a sequence of n variables and let $S \subseteq D$ be a set of domain values. Let $A = [a_1, \ldots, a_{k-1}]$ and $B = [b_1, \ldots, b_{k-1}]$ be sequences of natural numbers such that $a_i \leq b_i$ for $1 \leq i \leq k - 1$. Then* SPACING$_F(S, A, B, X)$ *holds iff* SPACING(S, A, B, X) *holds and all $S \subseteq \{X_1, \ldots, X_n\}$.*

This means that each value $v \in S$ occurs in the sequence on at least k different places.

Theorem 2. *Enforcing* DC *on the Global* SPACING$_F$ *Constraint is NP-hard.*

Proof (no minimal distance condition). We prove this by reduction of SAT to the problem of finding a support for SPACING$_F$. The reduction is the same as in the proof of Theorem 1, except the sequence X has additional $(c+2)(v+1)+1$ variables (in total $(2c+3)(v+1)$ variables) with domains as follows: If we order the variables into the same table as before, with rows of length $v+1$, the variables in the rest of the last column, as well as the variables in the $c+2$nd row can only take a dummy value 0

– the domains of variables $X_{j,v+1}$ for $c+1 \leq j \leq 2c+3$ and variables $X_{c+2,i}$ for $1 \leq i \leq v$ are $\{0\}$, where $0 \notin S$

and the first v cells of remaining $c+1$ rows are again the representation of propositional variables, so

– the domains of variables $X_{j,i}$ for $1 \leq i \leq v$ and $c+3 \leq j \leq 2c+3$ are again $\{p_i, \neg p_i\}$.

For example, the CNF $\phi = [\{\neg p, q, r\}, \{\neg q, r\}, \{\neg p, \neg q\}, \{p, q\}]$ from the previous example would be reduced to the constraint SPACING$_F(S, [1,1,1,1], [4,4,4,4], X)$ with $S = \{p, q, r, \neg p, \neg q, \neg r\}$ and X would contain 44 variables with domains ordered into the following table:

$i =$	1	2	3	4
$j = 1$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{\neg p, q, r\}$
$j = 2$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{\neg q, r\}$
$j = 3$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{\neg p, \neg q\}$
$j = 4$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{p, q\}$
$j = 5$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{0\}$
$j = 6$	$\{0\}$	$\{0\}$	$\{0\}$	$\{0\}$
$j = 7$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{0\}$
$j = 8$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{0\}$
$j = 9$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{0\}$
$j = 10$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{0\}$
$j = 11$	$\{p, \neg p\}$	$\{q, \neg q\}$	$\{r, \neg r\}$	$\{0\}$

We can divide the sequence into 2 parts separated by the $c+2$nd row. We will call the first one *positive* part and the second one *negative* part. If a value from S occurs in one part, it will occur at least $c+1$ times in that part, because the gap of 0-s between the parts is longer than any b_i, so all the necessary repetitions must occur in one part. Also if a value $d \in S$ occurs in one part, its complement $\overline{d}$ cannot occur in the same part because of a counting argument analogous to the one in the proof of Theorem 1, so, while all the values from S must occur in the support, the complement $\overline{d}$ must occur in the other part (where d will not occur due to the same argument).

Thanks to this, the proof of Theorem 1 holds for the positive part and the values that cannot occur in the positive part will occur in the negative part. It is obvious that there is enough space for all the values: $|S| = 2v$ while v values occur in the positive part

and the other v values occur in the negative part. Hence, we can obtain a support for the constraint from a model of ϕ and a model from a support in the same manner as in the proof of Theorem 1. □

As before, this proof does not make use of the condition on the minimal distance between two consecutive values from S (A is a sequence of 1-s). In fact, also if we relax the condition on the maximal distance between two consecutive values from S (B will be a sequence of n-s), the constraint is still intractable.

Theorem 3. *Enforcing* DC *on the Global* $\textsc{Spacing}_F$ *Constraint with* $b_i = n$ *for* $1 \leq i \leq k-1$ *is NP-hard.*

Proof (no maximal distance condition). We prove this by reduction of SAT to the problem of finding a support for SPACING. Let ϕ be an arbitrary CNF with v propositional variables and c clauses. There is a model of ϕ iff there is a support for the constraint $\textsc{Spacing}_F(S, [a_1, \ldots, a_{k-1}], [b_1, \ldots, b_{k-1}], X)$ with

- $S = lit(\phi)$
- $k = c$
- $a_i = 5v + 1$ and $b_i = (7v + 1)c$ for $1 \leq i \leq k - 1$
- X is a sequence of $(7v + 1)c$ variables with the domains as described below.

If we organize the variables from X into a table with c rows and $7v + 1$ columns, the first column will represent ϕ in the way that

- the domains of variables $X_{j,1}$ for $1 \leq j \leq c$ are C_j,

following $2v$ columns together with the first column will represent satisfied literals

- the domains of variables $X_{j,i+1}$ for $1 \leq i \leq v$ and $1 \leq j \leq c$ are $\{p_i, 0\}$ and
- the domains of variables $X_{j,i+(1+v)}$ for $1 \leq i \leq v$ and $1 \leq j \leq c$ are $\{\neg p_i, 0\}$,

following $2v$ columns will be a padding of 0-s

- the domains of variables $X_{j,i+(1+2v)}$ for $1 \leq i \leq 2v$ and $1 \leq j \leq c$ are $\{0\}$,

following v columns will represent unsatisfied literals

- the domains of variables $X_{j,i+(1+4v)}$ for $1 \leq i \leq v$ and $1 \leq j \leq c$ are $\{p_i, \neg p_i\}$

and the last $2v$ columns will be again a padding of 0-s.

- the domains of variables $X_{j,i+(1+5v)}$ for $1 \leq i \leq 2v$ and $1 \leq j \leq c$ are $\{0\}$.

For example, the CNF from our running example would be reduced to the constraint $\textsc{Spacing}_F(S, [16, 16, 16], [88, 88, 88], X)$ with $S = \{p, q, r, \neg p, \neg q, \neg r\}$ and X would contain 88 variables with domains ordered into the following table:

$i =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22
$j = 1$	$\neg p$ q r	p 0	q 0	r 0	$\neg p$ 0	$\neg q$ 0	$\neg r$ 0	0	0	0	0	0	0	p $\neg p$	q $\neg q$	r $\neg r$	0	0	0	0	0	0
$j = 2$	$\neg q$ r	p 0	q 0	r 0	$\neg p$ 0	$\neg q$ 0	$\neg r$ 0	0	0	0	0	0	0	p $\neg p$	q $\neg q$	r $\neg r$	0	0	0	0	0	0
$j = 3$	$\neg p$ $\neg q$	p 0	q 0	r 0	$\neg p$ 0	$\neg q$ 0	$\neg r$ 0	0	0	0	0	0	0	p $\neg p$	q $\neg q$	r $\neg r$	0	0	0	0	0	0
$j = 4$	p q	p 0	q 0	r 0	$\neg p$ 0	$\neg q$ 0	$\neg r$ 0	0	0	0	0	0	0	p $\neg p$	q $\neg q$	r $\neg r$	0	0	0	0	0	0

We can split the table into two parts. We will address the first $2v + 1$ columns as a *positive* part and the $4v + 2$nd to $5v + 1$-st column as a *negative* part. (The rest is padding of 0-s.) In order for an assignment to X to be a support, the following must hold:

- A value $d \in S$ can occur at most once per row because of the minimal distance condition imposed by the sequence A. While the number of rows is k, any value $d \in S$ has to occur in each row, so all values from S have to occur in each row exactly once.
- Two complementary values $d, \overline{d} \in S$ cannot occur in the same part of any row. For the negative part this is due to construction of the domains and if both occurred in the positive part, none of them would be able to occur in the negative part of the same row, so there would be a variable with empty domain, which is a contradiction.
- If a value from S occurs in one part of some row, it will occur in the same part in each row. This is because of the following:
  - If a value $d \in S$ occurs in the negative part of a row number j, it cannot occur in the positive part of the following row $j + 1$, because of the minimal distance condition, so it will occur in the negative part of the row $j + 1$.
  - Suppose a value $d \in S$ occurs in the positive part of a row number j. Then the complementary value $\overline{d}$ has to occur in the negative part of the row j. Now if $j \neq k$ and if the value d did not occur in the positive part of the following row $j + 1$, then it would have to occur in the negative part. Then, however, the complementary value $\overline{d}$ would not be able to occur in that negative part of the row $j + 1$, which is contradiction with the above. So d has to occur in the positive part of the row $j + 1$.
  - Each value from S has to occur in the first row. So if a value from S occurred in some row in a different part as in the first row, we would reach contradiction by applying the above.

Consequently, if we have a support of the constraint, the assignment to the first $2v+1$ variables (the positive part) represents a model of ϕ. The set of the values assigned to this variables (without the value 0) is clearly an interpretation, because it cannot contain complementary literals. Some value is selected for each variable representing clause (first column) and this value has to occur in the positive part of each row and its complement cannot occur in the positive part, hence the interpretation is also a model, because it contains at least one literal from each clause.

We can obtain a support of the constraint from a model I of ϕ by assigning a value that represents a literal that is satisfied by I to the variables in the first column. This is always possible, because I must satisfy at least one literal from each clause. The assignment to the variables in the positive part will be as follows: (1) The value 0 is assigned to the variable with domain containing value already assigned to the first variable in the row. (2) The literals satisfied by I are assigned to the rest of the variables as values. (3) Where this is not possible, 0 is assigned. This is always possible, because each literal that may occur in ϕ is represented by some value from the domains of these variables and no two representations of two different literals occur in a domain of one variable. Further, we assign the variables in the negative part so that they contain representations of each literal that is falsified by I. Such an assignment is always possible

because: (1) Each of these variables will be assigned, because I falsifies either p_i or $\neg p_i$ for each $1 \leq i \leq v$. (2) And there will be at most one possible value for each variable, because I is consistent. We assign 0 to the rest of the variables (their domains are $\{0\}$). Now the assignment is a support of the constraint, because each value $d \in S$ occurs exactly once in each row which is $c = k$ occurrences. Further, due to the fact that the representations of the satisfied literals occur always in the positive part and the representations of the falsified literals occur always in the negative part, there is always at least $5v$ places between two successive occurrences of each $d \in S$. In details, the last possible occurrence of a representation of a satisfied literal in the jth row is on the position $(j-1)(7v+1)+(2v+1)$ and the next possible occurrence of a representation of a satisfied literal is at the beginning of the following row $(j+1-1)(7v+1)+1$. The difference of these two positions is $5v+1 \geq 5v$. The last possible occurrence of a representation of a falsified literal in the jth row is on the position $(j-1)(7v+1)+(5v+1)$ and the next possible occurrence of a representation of a falsified literal is at the position $(j+1-1)(7v+1)+(4v+2)$ of the following row. The difference of these two positions is $6v+2 \geq 5v$. □

Another intractable restriction of the constraint is when all values from S are forced to occur on the first $p \leq n$ places, e.g. in the reduction from the last proof it was the first row. The following corollary summarizes all found intractable restrictions

Corollary 1. *Enforcing* DC *on the* SPACING *constraint is NP-hard even if any combination of the following not containing (3) and (4) simultaneously holds:*

(1) All the values from S must occur in the first $p \leq n$ places of the sequence.
(2) A and B are constant sequences, i.e. $a_1 = \ldots = a_k$ and $b_1 = \ldots = b_k$.
(3) There is no minimal distance condition ($a_i = 1$ for $1 \leq i \leq k-1$).
(4) There is no maximal distance condition ($b_i = n$ for $1 \leq i \leq k-1$).

Proof. The proof of Theorem 3 holds for all combinations of the restrictions not including (3) and the proof of Theorem 2 holds for all combinations of the restrictions not including (4). □

5 Bounded Size of S

We identified two useful restrictions of the SPACING constraint that allow polynomial time *DC* filtering algorithms. The first restriction bounds the size of S, $|S| = O(1)$. It can be used to model education process where the number of learning units is naturally bounded.

Theorem 4. *Enforcing* DC *on the* SPACING(S, A, B, X) *constraint can be done in* $O(n^{|S|+2}|S|)$ *time.*

Proof. We can define an automaton for accepting sequences satisfying the SPACING constraint. The states of the automaton just need to keep count of the number of steps since the last occurrence of each value in S. There are $O(n^{|S|})$ possible states in this automaton, which is polynomial for $|S| = O(1)$. □

6 The One Voice Global SPACING Constraint (SPACING1)

The second tractable restriction of the SPACING constraint ensures that all values from S occur in the first *period* of length p and they must repeat in the successive $k-1$ periods on the same *places*. In other words, the first period of length p is cycled k times. This restriction is useful in music composition problems [6], where the composer wants to generate one voice consisting of a p beat long rhythmical pattern that is played k times. The pattern consists of $|S|$ onsets (beginnings of notes) that must be played exactly k times in the whole voice. This can be encoded using a restriction of SPACING that is defined as follows:

Definition 3. *Let $X = [X_1, \ldots, X_n]$ be a sequence of n variables and let $S \subseteq D$ be a set of domain values. Let p and k be natural numbers such that $p \leq n$ and $pk \leq n$. Then* SPACING1(S, p, k, X) *holds iff* SPACING(S, A, B, X) *with $S \subseteq \{X_1, \ldots, X_p\}$, $a_i = b_i = p$ for $1 \leq i \leq k-1$ and $|\{j \mid X_j = d, 1 \leq j \leq n\}| = k$ for all $d \in S$ holds.*

Theorem 5. *For any constraint* SPACING1(S, p, k, X)*, there is a bipartite graph $G = (U, V, E)$ such that there is a support for the constraint iff there is a maximum matching in G. Enforcing* DC *on the constraint takes $O(p^2k + p^{2.5})$ time down a branch of the search tree.*

Proof. First, we observe that values $D \setminus S$ are interchangeable as we do not distinguish between values d outside S, $d \notin S$. Therefore, we perform channeling of variables X to variables Y and map all values outside of S into a dummy value 0: $X_i \in S \leftrightarrow Y_i = X_i$ and $X_i \notin S \leftrightarrow Y_i = 0$ for $1 \leq i \leq n$, where $0 \notin S$ is a fresh value.

Second, we exploit the special structure of SPACING1. Namely, variables in positions $i, p+i, \ldots, (k-1)p+i$, $1 \leq i \leq p$, must take the same value. Hence, to check whether value d can be assigned to one of the variables $Y_i, Y_{p+i}, \ldots, Y_{(k-1)p+i}$, we need to check whether $d \in \bigcap_{j=0}^{k-1} D(Y_{jp+i})$. We use a *folding* procedure to identify possible positions for each value. We *fold* the domains of Y into $P_i = \bigcap_{j=0}^{k-1} D(Y_{jp+i})$ for $1 \leq i \leq p$.

Finally, we need to match values $S \cup \{0\}$ with the positions in one period. To avoid using generalized matching, we introduce $p - |S|$ copies of the dummy value, otherwise we would have to match 0 with $p - |S|$ nodes.

Next we describe construction of the graph G. The sets of nodes are $U = S \cup \{0_j \mid 1 \leq j \leq p - |S|\}$, $V = \{1, \ldots, p\}$. The set of edges is $E = \{(d, i) \mid d \in P_i \cap S, 1 \leq i \leq p\} \cup \{(0_j, i) \mid 1 \leq j \leq p - |S|, 0 \in P_i, 1 \leq i \leq p\}$. Now we show that there exists a support for SPACING1 iff there exists a maximum matching in G.

Having a support for the constraint, we can obtain a subgraph of G with the same sets of nodes and the set of edges M that consists of two parts: (1) the edges between the places of the variables in the first period and the values from S that are assigned to them in the support $M_1 = \{(d, i) \mid d = X_i, d \in S, 1 \leq i \leq p\}$, (2) if we order the rest of the places in the first period (that contain values not in S) into a new sequence $N = [i | X_i \notin S, 1 \leq i \leq p]$ (note that $|N| = p - |S|$), the edges between these places and the dummy values with the same index $M_2 = \{(0_j, N_j) \mid 1 \leq j \leq p - |S|\}$. So $M = M_1 \cup M_2$. Now we have indeed a subgraph of G, because M is a subset

of E, because, while we have a support, values from S have to repeat on the same places in each period, so $X_i \in P_i$ if $X_i \in S$ and $0 \in P_i$ if $X_i \notin S$ for $1 \leq i \leq p$, thus $M_1 \subseteq \{(d,i) \mid d \in P_i \cap S, 1 \leq i \leq p\}$ and $M_2 \subseteq \{(0_j,i) \mid 1 \leq j \leq p-|S|, 0 \in P_i, 1 \leq i \leq p\}$. M is also a matching in G, because exactly one value is assigned to each variable and each dummy value is connected to exactly one place. M is a maximum matching, because it contains all the nodes, because each value from S have to be assigned to some variable in the first period and the number of the dummy values is exactly the number of variables in the first period with values not in S assigned to them. Hence, we obtained a maximum matching in G from a support for the constraint.

Now having a maximum matching M in G, we can obtain a support for the constraint by assigning the values from S to the places in each period to which they are matched by M and any value not in S to the places in each period to which a dummy value is matched by M. This is a valid assignment, because M matches something with each place, because it is maximal. This assignment is always possible, because G connects each $d \in S$ only to places of variables with domains containing d in each period and G connects dummy values only to places of variables with domains containing a value not in S in each period. The assignment is indeed a support, because each value from S is matched with exactly one place of a period and repeats altogether k times on the same place in each period.

Our *DC* propagator is based on *DC* propagator for ALLDIFFERENT by Regin[4]. First, we determine the set of edges that do not belong to any maximum matching the same way as propagator for ALLDIFFERENT enforces *DC*. This takes $O(p^{2.5})$ down a branch of the search tree. If an edge (u,i) does not belong to any matching then the value u can be removed from domains of variables $Y_i, Y_{p+i}, \ldots, Y_{(k-1)p+i}$ which takes $O(k)$ time. There can be at most $O(p^2)$ removals down a branch, so overall complexity down a branch of the search tree is $O(p^2k + p^{2.5})$. □

For example, consider the SPACING1 constraint with $D = \{a,b,c,o\}$, $S = \{a,b,c\}$ representing the onsets, $p = 5$ length of the pattern and $k = 3$ number of repetitions on the sequence of 15 variables. The variable domains are as shown below:

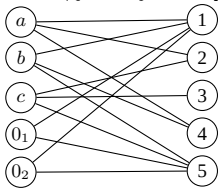

$i =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
$D(X_i) =$	a b o	a b c o	a b c o	a b 	 b c o	a b c o	a b c 	 c 	a b c o	 b c o	a b c o	a c o	a b c o	a b c o	 b c o

During propagation, channeling will simply replaces o with 0. Then the folded domains will look like this:

$i =$	1	2	3	4	5
$P_i =$	a b 0	a c	 c	a b 	b c 0

And finally, the bipartite graph is given in Figure 1. There are two maximum matchings in this graph: $\{(c,3),(a,2),(b,4),(0_1,1),(0_2,5)\}$ and $\{(c,3),(a,2),(b,4),(0_2,1),(0_1,5)\}$. This means that the only support is $[o,a,c,b,o,o,a,c,b,o,o,a,c,b,o]$.

Fig. 1. A bipartite graph for SPACING1($\{a, b, c\}, 5, 3, [X_1, \ldots, X_{15}]$) from the example

7 The h-Voice Global SPACING Constraint (SPACING$_h$)

A composer would usually want to compose more voices playing at the same time with no overlapping onsets. The h-Voice Global SPACING Constraint, which is simply a conjunction of more SPACING1 constraints on the same sequence of variables, can be used for this purpose.

Definition 4 (SPACING$_h$). *Let $X = [X_1, \ldots, X_n]$ be a sequence of n variables and let $S = [S_1, \ldots, S_h]$ be a sequence of pairwise disjoint sets of domain values ($\bigcup_{l=1}^{h} S_l \subseteq D$ and $S_{l_1} \cap S_{l_2} = \emptyset$ for all $1 \leq l_1 < l_2 \leq h$). Let $[p_1, \ldots, p_h]$ be a sequence of natural numbers and let k be a natural number such that $p_l k \leq n$ for all $1 \leq l \leq h$. Then* SPACING$_h(S, [p_1, \ldots, p_h], k, X)$ *holds iff a conjunction of constraints* SPACING1(S_l, p_l, k, X) *for all $1 \leq l \leq h$ holds.*

Theorem 6. *Enforcing* DC *on the Global* SPACING$_h$ *Constraint is NP-hard even for $h = 2$.*

Proof. We prove this by reduction of SAT to the problem of finding a support for SPACING$_h$. The main idea of the proof is similar to the other hardness proofs: The alternative choice of a literal satisfying a clause is modeled by choice of a value for a variable and mutual exclusion of complementary literals is enforced by properties of SPACING. For the SPACING$_h$ constraint it is mutual exclusion of values from the same variable domain (assignment of one excludes the others). The system how choosing two complementary literals to be true leads to the mutual exclusion of values is quite complicated, because we have little freedom (just two voices). The idea is that the literal chosen to satisfy a clause is copied to the part representing the model. This is done by the impossibility of having more than one occurrence of the same value in one period of a voice, so from domains of cardinality 2 containing this value the other one has to be chosen. These other values (that represent the model) belong, however, to the other voice, which has period of different length, so repetitions of these values will be aligned with different places of the other periods of the first voice. On the one hand, this is used for copying the clause satisfiers to the same model representation, on the other hand, it is used to align values for complementary literals with each other so that their assignment mutually exclude each other.

Now we describe the reduction in detail. Please, recall that if L is a set of literals, then $L' = \{l' \mid l \in L\}$ and $L^i = \{l^i \mid l \in L\}$. Let ϕ be an arbitrary CNF with v propositional variables and c clauses. There is a model of ϕ iff there is a support for the constraint SPACING$_h([S_1, S_2], [p_1, p_2], k, X)$ where

- $S_1 = lit(\phi)' \cup \bigcup_{j=1}^{c} \left(lit(\phi)^j\right)$
- $S_2 = lit(\phi)$
- $p_1 = c + 6cv$
- $p_2 = c + 6cv + 2v$
- $k = c$
- X is a sequence of $(c + 6cv + 2v)k$ variables with the domains as described below.

We will describe the domains voice by voice, so ultimately the domains are minimal sets satisfying the following conditions. The period of the first voice is $p_1 = c+6cv$, let us split the sequence into rows of this length and order them into a table (one row is one period of the first voice). Let $X^1_{j,i}$ denote $X_{(j-1)p_1+i}$. Then the first c columns represent ϕ in the following fashion: The cells on the main diagonal represent the clauses and the other cells are filled with representation of all the literals,

- the domains of variables $X^1_{j,i}$ for $1 \leq j, i \leq c$ contain $\{p^i \mid p \in C_j\}$ if $i = j$, otherwise $lit(\phi)^i$.

The following $4cv$ columns contain representations of all literals for each clause two times,

- the domains of variables $X^1_{j,(c)+(i-1)2v+vy+x}$ for $1 \leq j, i \leq c$, $0 \leq y \leq 1$ and $1 \leq x \leq v$ contain p^i_x if $y = 0$ and $\neg p^i_x$ if $y = 1$,
- the domains of variables $X^1_{j,(c+2cv)+(i-1)2v+vy+x}$ for $1 \leq j, i \leq c$, $0 \leq y \leq 1$ and $1 \leq x \leq v$ contain p^i_x if $y = 0$ and $\neg p^i_x$ if $y = 1$.

The last $2cv$ columns contain representations of all literals in the usual order in their first $2v$ columns, in their last $2v$ in the order where positive and negative literals are swapped, and 0 in the rest of their columns,

- the domains of variables $X^1_{j,(c+4cv)+x}$ for $1 \leq j \leq c$ and $1 \leq x \leq v$ contain p'_x,
- the domains of variables $X^1_{j,(c+4cv)+v+x}$ for $1 \leq j \leq c$ and $1 \leq x \leq v$ contain $\neg p'_x$,
- the domains of variables $X^1_{j,(c+4cv)+2v+x}$ for $1 \leq j \leq c$ and $1 \leq x \leq 2cv - 4v$ contain 0,
- the domains of variables $X^1_{j,(c+4cv)+(2cv-2v)+x}$ for $1 \leq j \leq c$ and $1 \leq x \leq v$ contain $\neg p'_x$,
- the domains of variables $X^1_{j,(c+4cv)+(2cv-v)+x}$ for $1 \leq j \leq c$ and $1 \leq x \leq v$ contain p'_x.

(This is not well defined for $c = 1$, but ϕ is trivially satisfiable in this case.) The arrangement of the values of the second voice is much more simple. The period of the second voice is $p_2 = c + 6cv + 2v$, so let $X^2_{j,i}$ denote $X_{(j-1)p_2+i}$. Then places from $c + 1$ to $c + 2v$ and from $c + 4cv + 1$ to $c + 4cv + 2v$ of each period contain representations of all literals in the usual order,

- the domains of variables $X^2_{j,(c)+x}$ for $1 \leq j \leq c$ and $1 \leq x \leq v$ contain p_x,
- the domains of variables $X^2_{j,(c+v)+x}$ for $1 \leq j \leq c$ and $1 \leq x \leq v$ contain $\neg p_x$,

– the domains of variables $X^2_{j,(c+4cv)+x}$ for $1 \leq j \leq c$ and $1 \leq x \leq v$ contain p_x,
– the domains of variables $X^2_{j,(c+4cv+v)+x}$ for $1 \leq j \leq c$ and $1 \leq x \leq v$ contain $\neg p_x$.

Finally, the domains of variables that are not on the first c places of any period of the first voice and do not contain a value from S_2 contain 0:

– the domains of variables X_i for $i \notin \{(j-1)p_1 + x \mid 1 \leq j, x \leq c\} \cup \{(j-1)p_2 + c + x \mid 1 \leq j \leq c, 1 \leq x \leq 2v\} \cup \{(j-1)p_2 + c + 4cv + x \mid 1 \leq j \leq c, 1 \leq x \leq 2v\}$ contain 0.

The constraint for the CNF from our running example would be imposed on a sequence of variables with domains displayed in the Table 1. The last $2vk$ domains of $\{0\}$ are not displayed in the table.

Let us organize the sequence X into a table with $c + 6cv$ columns again (using $X^1_{j,i}$ notation) and ignore the last $2cv$ variables with domains $\{0\}$. Each row belongs to one clause. Also there is one set of literal representing values for each clause ($lit(\phi)^j$ for C_j). Clauses form domains on the main diagonal using their sets of values. The rest of the domains in the first c columns are constructed to enable repetitions of values selected for the clause variables. The next $2cv$ columns are called *positive* part, because the values from S_2 it contains will represent a model of ϕ. Due to the difference between periods, in each row j these values from S_2 are aligned with the values of the clause of the row (values from $lit(\phi)^j$). Thanks to this, when a value d^j is assigned to the variable of clause C_j, d^j cannot occur in the rest of the row, thus also not in the positive part, so the appropriate value d has to be selected in this part. This is why, having a solution of the constraint, at least one literal from each clause will be assigned as a value from S_2 to some variable in the positive part.

The last $2cv$ columns are *consistency* part, because they ensure the consistency of the model represented by a solution. When a value $d \in S_2$ is assigned to a variable in the positive part, it has to be repeated in the positive part in each row. Also it cannot be repeated in the rest of any row. Hence a corresponding primed value $d' \in S_1$ must be assigned to one of the first $2v$ places of the consistency part of the first row (and also each other row), thus d' cannot repeat in the last $2v$ places of the consistency part in any row, mainly not in the last one. Please note that the positive and negative primed values are switched in the last $2v$ places, so that, in the last row, the negative primed values are aligned with the positive values from S_2 and the positive ones are aligned with the negative ones. This whole construction of the domains causes that if two complementary literal values $d, \overline{d} \in S_2$ are assigned to variables in the positive part, they cannot be assigned to the first $2v$ variables in the first row of the consistency part, so both $d', \overline{d'} \in S_1$ have to be assigned in these first $2v$ variables and cannot be assigned to the last $2v$ variables in the last row of the consistency part. However, the same assignment of values from S_2 must be repeated in each row of this part, so two variables in the last $2v$ places of the last row would be left with empty domains. Analogous reasoning rules out the case when none of $d, \overline{d} \in S_2$ is assigned in the positive part. Also it is easy to see that when exactly one of $d, \overline{d} \in S_2$ is assigned in the positive part, no contradiction is reached. This shows that, having a solution of the constraint, the set of literals assigned as a values from S_2 in the positive part is

Table 1. Example for reduction from SAT to SPACING$_h$.

consistent. So, together with the result above, having a solution of the constraint, the set of literals assigned as a values from S_2 in the positive part is a model of ϕ.

We can obtain a solution of the constraint from a model of ϕ in the following way: We assign the literals from the model as a values of the second voice to the variables in the positive part. Then we choose a value that represents some literal satisfied by the model for the clause variables. And assign the rest of the variables so that the constraint holds. It is always possible to do this. It is always possible to assign the literals from the model to the positive part, because there is one variable for each literal in each row of the part and these variables repeat with the period of the second voice (where the values are from). It is always possible to complete the assignment to the positive part, because each value has an alternative in each domain and each value can be repeated with it's period. As long as the model is consistent, no contradiction can be reached in the consistency part because of the following: For any pair of complementary literals $d, \overline{d} \in S_2$, one of them is assigned in the positive part and the other one is not. The selection of the values from S_2 in the consistency part is reversed with comparison to the positive part, so the mutual exclusion still holds. The selection of the primed values in the first $2v$ columns of the consistency part will represent the model again and the selection of the primed values in the last $2v$ columns will be reversed again. Due to the fact that the positive values are swapped for the negative ones in the last $2v$ columns, assignment of the primed values complements the assignment of values from S_2 in the first as well in the last $2v$ columns and no domains are emptied. It is always possible to select some value for the clause variables because of the following: In the positive part of each row j, the selection of the values indexed with j will be complementary to the selection of the values from the model. This leaves the possibility for the indexed values representing literals satisfied by the model to be selected elsewhere in the row, for instance in the clause variable. Each clause variable always contains at lease one value representing literal satisfied by the model. Assignment to the clause variables can be repeated in each row and the primed values that could not be selected in the positive part nor in the clause values can still be assigned to some of the variables in the columns between $c + 2cv + 1$ and $c + 4cv$ called *negative* part. □

8 Incomplete filtering of SPACING$_h$

Since already a conjunction of two SPACING1 constraints is NP-hard, we decided to devise an incomplete additional rule that facilitates propagation between two SPACING1 constraints on the same sequence. If periods of these two constraints are of different length, assigning a value from the first one to one variable forbids assigning any value from the second one to multiple variables. For example, take SPACING1$(\{a, b\}, 5, 4, X)$ and SPACING1$(\{c, d\}, 7, 3, X)$ on the same sequence X of 21 variables. We start with full domains for all variables. After assign a to the first variable and filtering the domains are:

$i =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21
$D(X_i) =$	a	b 0	b c d 0	b 0	b c d 0	a	b c d 0	b 0	b 0	b c d 0	a	b c d 0	b 0	b c d 0	b 0	a	b c d 0	b 0	b c d 0	b 0	c d 0

If we assign b to X_4, the assignment must be repeated every 5 variables. These repetitions occur on different places of the second period, so sufficient number of repetitions of c and d will not be possible. Subsequent filtering would remove circled values

$i =$	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21
$D(X_i) =$	a	ⓑ	ⓑ	b	ⓑ	a	ⓑ	ⓑ	b	ⓑ	a	ⓑ	ⓑ	b	ⓑ	a	ⓑ	ⓑ	b	ⓑ	
			c		ⓒ		ⓒ			c		ⓒ		ⓒ			c		ⓒ		ⓒ
			d		ⓓ		ⓓ			d		ⓓ		ⓓ			d		ⓓ		ⓓ
		0	0	Ⓘ	0		0	0	Ⓘ	0		0	0	Ⓘ	0		0	0	Ⓘ	0	0

and render the second constraint unsatisfiable. The same course of reasoning holds for assigning b to X_2 and X_5. Thus only possibility is to assign b to X_3, which leaves only two places free in the period of the second SPACING1, hence two symmetrical solutions.

Formally, we first need to count a number of places that may contain a value from S_l for each SPACING1 constraint l. We denote it by u_l and define as

$$u_l = |\{i \mid S_l \cap P_i^l \neq \emptyset, 1 \leq i \leq p_l\}|$$

where P_i^l are the folded domains from the proof of Theorem 5 for the constraint l. Now we need to count a number of places that are not blocked for values from S_{l_2}, but would become blocked after assigning a value from S_{l_1} to a variable X_i in the first period of l_1 (i.e. $1 \leq i \leq p_{l_1}$). This count is denoted by $b_i^{l_1,l_2}$ and defined as

$$|\{x \mid x = ((i+jp_{l_1}-1) \bmod p_{l_2})+1, 0 \leq j < k_{l_1}, i+jp_{l_1} \leq k_{l_2}p_{l_2}, S_{l_2} \cap D(X_x) \neq \emptyset\}|$$

for each pair of different voices l_1, l_2 and $1 \leq i \leq p_{l_1}$.

Theorem 7. *Let $l_1 = \text{SPACING1}(S_{l_1}, p_{l_1}, k_{l_1}, X)$ and $l_2 = \text{SPACING1}(S_{l_2}, p_{l_2}, k_{l_2}, X)$ be two constraints defined on the same sequence X with $S_{l_1} \cap S_{l_2} = \emptyset$ that are* DC*. Let u_{l_2} and $b_i^{l_1,l_2}$ be defined as above. If $b_i^{l_1,l_2} > u_{l_2} - |S_{l_2}|$ then there is no support for $l_1 \wedge l_2$ with any value from S_{l_1} assigned to X_i within $1 \leq i \leq p_{l_1}$.*

Proof. Suppose the premises of the theorem hold. The places in the first period of l_2 that may hold a value from S_{l_2} (together with places that already hold it) are called *free*. The rest of the places in the first period of l_2 are called *blocked*. The number of the free places is u_{l_2}. Suppose that we assigned a value $d_1 \in S_{l_1}$ to X_i. Then d_1 has to repeat on the same place in each period of l_1, that is places $i + jp_{l_1}$ for each $0 \leq j < k_{l_1}$. Now no value from S_{l_2} can be put on those of these places that are constrained by l_2, i.e. $i + jp_{l_1} \leq k_{l_2}p_{l_2}$ for $0 \leq j < k_{l_1}$. So no value from S_{l_2} can repeat on whatever places in the period p_{l_2} these places are aligned with. Arbitrary index y into the sequence X is $((y-1) \bmod p_{l_2}) + 1$-st place in a period of l_2, so no value from S_{l_2} can be assigned to any variable with index $x = ((i + jp_{l_1} - 1) \bmod p_{l_2}) + 1$ where $i + jp_{l_1} \leq k_{l_2}p_{l_2}$ for $0 \leq j < k_{l_1}$. While l_2 is *DC* and $1 \leq x \leq p_{l_2}$, $S_{l_2} \cap D(X_x) = S_{l_2} \cap P_x^{l_2}$. This restricts the places we are counting in $b_i^{l_1,l_2}$ to those that were free, so $b_i^{l_1,l_2}$ is the number of places that are blocked exclusively by assigning d_1 to X_i. Finally, suppose $b_i^{l_1,l_2} > u_{l_2} - |S_{l_2}|$ holds. This is equivalent to $u_{l_2} - b_i^{l_1,l_2} < |S_{l_2}|$ which means that the number of free places without the places blocked solely by d_1 on the place i (the places left free after the assignment) is less than the number of values from S_{l_2} we need to assign to one period of l_2. The constraint l_2 is obviously unsatisfiable in this case, so there is no support for $l_1 \wedge l_2$ with any value $d \in S_{l_1}$ assigned to X_i. □

9 Application

One of the applications of CSP in music composition is the problem of *Asynchronous rhythms* described by Truchet [5,6]. Having h voices and a time horizon H, the goal is to construct one rhythmical pattern for each voice. The patterns are played repeatedly until the time horizon is reached. The pattern of voice l is of length p_l and consists of m_l onsets that have to be placed so that no two onsets are played at the same time. We consider also extension of this problem, where composer may want to impose additional constraints, such as forbidding or enforcing particular onsets on particular places, or restricting the density of the onsets e.g. at most one onset on two successive places.

Truchet [5,6] formalized this problem in terms of variables $V_{l,i}$ that denote time when an onset i is played in the pattern of voice l (so $D(V_{l,i}) = \{1, \ldots, p_l\}$) and the following constraints: ALLDIFFERENT$(\{V_{l,1}, \ldots, V_{l,m_l}\})$ for each voice l, and $V_{l_1,i_1} + j_1 p_{l_1} \neq V_{l_2,i_2} + j_2 p_{l_2}$ for each pair of different voices l_1, l_2, each onset i_1, i_2 in each voice respectively and each j_1, j_2 s.t. $V_{l_1,i_1} + j_1 p_1 \leq H$ and $V_{l_2,i_2} + j_2 p_2 \leq H$. This, however, cannot be encoded as a CSP model, because if $H \bmod p_l \neq 0$ for some voice l then the range of j_l in the later constraint depends on $V_{l,i}$ for each onset i. We fix this by minor modification, where the pattern of each voice l is repeated exactly k_l times and the indexes j_1, j_2 in the last constraint are quantified by $0 \leq j_1 < k_{l_1}$ and $0 \leq j_2 < k_{l_2}$. We will call this model OM.

We encoded the problem into three new models. The first model (SM) uses one SPACING1(S_l, p_l, k_l, X) for each voice l on the same sequence of variables X. The sets of values S_l represent the onsets for each voice l, so they must be pairwise disjoint. The length of the pattern of voice l is p_l and the number of its repetitions is k_l. Each variable X_j represents the onset played in the beat j, so $D(X_j) = \bigcup_{l=1}^{h} S_l \cup \{0\}$ where $0 \notin \bigcup_{l=1}^{h} S_l$.

Theorem 8. *Enforcing* DC *on* SM *is strictly stronger than enforcing* DC *on* OM.

Proof. First we show that if every constraint in SM is *DC*, then also every constraint in OM is *DC*.

Suppose every constraint in SM is *DC*.

The first question is what is the correspondence between the two models in this case, i.e. if SM is *DC*, with what domains should we check OM for *DC*. The correspondence should be semantical. That is, for every placing of every onset whether it is possible to place other onsets so that each constraint of a model is satisfied. While all the SPACING1 constraints are *DC*, the domains restricted to their values are the same in each of their period. So the correspondence between the models can be described only on the first periods. It is $d \in D(X_i)$ where $d \in S_l$ and $1 \leq i \leq p_l$ iff $i \in D(V_{l,d})$.

If every constraint in SM is *DC*, then also every ALLDIFFERENT in OM is *DC*, because the bipartite graph in the propagator of SPACING1 of voice l is a supergraph of ALLDIFFERENT for voice l in OM. So while the SPACING1 is *DC*, all edges in its graph belong to some maximum matching. If we remove each 0 node, we obtain a graph of the corresponding ALLDIFFERENT. Each of the edges in the new graph still belong to some maximum matching in it, because removing nodes preserves maximum matchings, because while each edge is in some maximum matching and each node is

in at most one edge of a matching, each maximum matching loses exactly one edge per removed node.

If every constraint in SM is *DC*, then also every difference constraint in OM is *DC*. The semantics of a difference constraint $V_{l_1,i_1} + j_1 p_{l_1} \neq V_{l_2,i_2} + j_2 p_{l_2}$ is that the onset i_1 in the j_1+1-st period of the voice l_1 cannot be played at the same time as the onset i_2 in the $j_2 + 1$-st period of the voice l_2. If a difference constraint was not *DC*, this would mean that for some placing of the onset i_1 it is not possible to place the onset i_2 so that they would be played on different times in the $j_1 + 1$-st and $j_2 + 1$-st periods of their voices respectively. This is possible only if the placing of i_2 is fixed ($D(V_{l_2,i_2}) = \{x\}$). This, however, means in the SM that the value of this onset has only one place where it can occur in one period of l_2 ($i_2 \in D(X_y)$ iff $y = x$ for $1 \leq y \leq p_{l_2}$), so the propagator of SPACING1 for this voice would instantiate it and hence remove other values from the domain of the variable of the place ($D(X_x) = \{i_2\}$). This means for SPACING1 of l_1 instantiating the variable of the place to 0 ($D(Y_x^{l_1}) = \{0\}$), so assuming SM is *DC* we have contradiction with possibility of placing i_1 so that the difference constraint cannot be satisfied ($x \notin D(V_{l_1,i_1})$ because $i_1 \notin D(Y_x^{l_1}) = \{0\}$), so the difference constraint must be *DC*.

To show strictness, consider instance of *Asynchronous rhythms* with two voices, first having $m_1 = p_1 = k_1 = 2$ and the second one $m_2 = 1$, $p_2 = 3$, $k_2 = 2$. Additionally, the very first place has to contain an onset of the first voice. Domains of variables of OM for this instance are $D(V_{1,a}) = D(V_{1,b}) = \{1, 2\}$ and $D(V_{2,c}) = \{2, 3\}$ and the constraints are ALLDIFFERENT($\{V_{1,a}, V_{1,b}\}$) and $V_{1,i} \neq V_{2,c}$, $V_{1,i} + 2 \neq V_{2,c}$, $V_{1,i} \neq V_{2,c} + 3$, $V_{1,i} + 2 \neq V_{2,c} + 3$ for $i \in \{a, b\}$. All the constraints of this model are *DC*. However, domains of variables of SM are $D(X_1) = \{a, b\}$ and $D(X_2) = \ldots = D(X_6) = \{a, b, c, 0\}$ where $S_1 = \{a, b\}$ and $S_2 = \{c\}$. The propagation of SPACING1 for the first voice will remove all values not in S_1 from $D(X_2)$ up to $D(X_4)$. This leaves the SPACING1 for the second voice unsatisfiable. So SM determines that the instance is unsatisfiable without search while OM is not able to do so. □

Drawback of SM is that, due to interchangeability of onsets in one voice, it generates a lot of symmetrical solutions. This observation led to the second model (SB). It is the same as the first one, except it uses a version of SPACING1 that does not distinguish between different values in one voice, which is a piece of information a composer does not need when constructing rhythmical patterns. This new constraint, denoted SPACING$_{SB}(d, m, p, k, X)$, can be defined as SPACING1(S, p, k, X) where S is a multiset of m values d. In other words, SPACING$_{SB}(d, m, p, k, X)$ is satisfied iff there is exactly m occurrences of d in the first p places of X and this pattern is repeated k times. Filtering algorithm of SPACING$_{SB}$ takes $O(n)$ time down a branch of a search tree as we can avoid finding the maximum matching step. After folding of the domains $P_i = \bigcap_{j=0}^{k-1} D(X_{jp+i})$ for $1 \leq i \leq p$, the filtering algorithm simply counts $u = |\{i \mid d \in P_i, 1 \leq i \leq p\}|$ and $v = |\{i \mid P_i = \{d\}, 1 \leq i \leq p\}|$. The algorithm fails iff $u < m$ or $v > m$, if $u = m$ it instantiates all X_i with $d \in D(X_i)$ to d and if $v = m$ it removes d from all domains that $D(X_i) \neq \{d\}$. Of course, the algorithm reflects the folded domains P_i back to the domains $D(X_i)$ by removing d if $d \notin P_i$ or instantiating to d if $P_i = \{d\}$ and repeats all the instantiations and all the removals on the appropriate places in each period.

Theorem 9. *Enforcing* DC *on* SPACING$_{SB}$ *can be done in* $O(n)$ *time down a branch of the search tree.*

Proof. In order to show that the filtering algorithm described above really establishes *DC*, we need to show that it fails iff the constraint is unsatisfiable and if it does not fail the constraint is *DC*.

Thanks to the folding of the domains, reflecting the folded domains back and repetition of instantiations and removals in each period, for the domains on the same places of each period ($\{D(X_{jp+i}) \mid 0 \leq j < k\}$ for each i) it holds that one contain d or is $\{d\}$ iff all the others contain d or are $\{d\}$ respectively. This allows us to restrict out reasoning only to one period.

First, we show that the algorithm fails iff the constraint is unsatisfiable. After what is shown in the previous paragraph the only way how to falsify the constraint is to put either too many or too little values d to one period. Obviously, $u < m$ means that there is not enough variables in one period with d in their domains and $v > m$ means that d is assigned to too many variables in one period. So $u < m$ or $v > m$ holds iff the constraint is unsatisfiable, so the algorithm fails iff the constraints is unsatisfiable.

Second, we show that if the algorithm removes a value from the domain of a variable, there is no solution of the constraint with this value assigned to this variable. Suppose the algorithm removes d from $D(X_i)$. Except the cases considered in the first paragraph, the algorithm does so only when $v = m$ and i is not one of the places counted in v. So if there was a solution with $X_i = d$, the number of occurrences of d in one period would be $m + 1$, which is a contradiction. Suppose the algorithm removes $d' \neq d$ from $D(X_i)$. Except the cases considered in the first paragraph, the algorithm does so only when $u = m$ and i is one of the places counted in u. So if there was a solution with $X_i = d'$, the number of occurrences of d in one period would be $m - 1$, which is a contradiction.

Finally, we show that if the constraint is satisfiable and there is no solution of the constraint with a value assigned to a variable, the algorithm removes the value from the domain of the variable. Suppose the constraint is satisfiable and there is no solution of the constraint with a value d' assigned to a variable X_i. Except the cases considered in the first paragraph, the constraint may have no solution only in two cases: The value d is assigned to too many or too little variables in one period. The constraint is satisfiable without the assignment $X_i = d'$. So the first case is possible only if there are exactly m variables in one period with d assigned to them and the assignment $X_i = d'$ increases this number. This means that X_i is not instantiated to d yet, $d' = d$ and $v = m$ holds, so the algorithm will remove d from the domains of all the variables that are not instantiated to d yet, hence also from $D(X_i)$. The second case is possible only if there are exactly m variables in one period with d in their domains and the assignment $X_i = d'$ decreases this number. This means that X_i contains d in its domain, $d' \neq d$ and $u = m$ holds, so the algorithm will assign d to all the variables that contain d in their domains, hence remove d' from $D(X_i)$.

The algorithm runs in $O(n)$ time down a branch of the search tree, because the folded domains P_i are represented implicitly. At the beginning of the search, folding and reflecting back to the domains takes $O(pk)$, because it is done simply by, for every $1 \leq i \leq p$, removing d from each $D(X_{jp+i})$, $0 \leq j < k$ if it is missing in some and

instantiating each X_{jp+i}, $0 \leq j < k$ to d if some already is instantiated. During the search it is sufficient just to update u and v upon removal of d or instantiation to d. On each update, the same action (removal or instantiation) has to be repeated in each of k period. Down a branch there will be at most p such updates, because after p updates the pattern of d-s in a period is fully determined. That makes $O(pk)$ steps down a branch. While $pk \leq n$, the filtering runs in $O(n)$ time down a branch of the search tree. □

The last model (SR) is the same as SM, but it is additionally making use of the incomplete filtering rule for SPACING$_h$ (described in the previous section) between each pair of constraints.

10 Experimental results

To compare performance of the different models, we carried out a series of experiments on random instances of the *Asynchronous rhythms* problem. The instances were generated for a fixed number of voices h, a mean length of the pattern of the first voice p_1 and a fixed number of repetitions of the last voice k_h. The models were tested on ten instances for each tuple of (h, p_1, k_h). The generation of the instances followed the philosophy that the first voice should be the base voice with short pattern and small number of onsets and the other voices should have richer patterns. So the pattern of the second voice was 4 ± 1 beats longer that the pattern of the first voice and each following voice had pattern in average two times longer ± 3 beats than two voices before. Numbers of repetitions were set so that the voices overlap as much as possible. And the total number of the onsets was approximately 75% of the length of the sequence uniformly distributed between the voices. The experiments were run with 5 minute timeout and with a heuristic under which all models were performing better. The left side of Table 2 shows performance of the models on the *basic* Asynchronous rhythms problem. The right side of Table 2 shows performance of the models on the *extended* Asynchronous Rhythms problem, where the composer applies additional constraints that some onsets are forbidden in certain positions. We randomly removed 10% of values from the domains to model this restriction. SB was not tested on the extended problem, because in this case onsets are not interchangeable due to additional constraints on onsets. Experiments were run with CHOCO Solver 2.1.5 on Intel Xeon 3 CPU 2.0Ghz, 4GB RAM.

As we can see in the results, SB solved almost all instances and, where comparable, it was the fastest and needed the least backtracks in solving basic model. SB is so successful because it removes symmetries and the filtering algorithm of SPACING$_{SB}$ runs in $O(n)$ down a branch. On the basic problem, SM is not obviously better than OM, however SM performs much better on the extended problem and it needs significantly less backtracks than OM. That supports the theory that SM achieves more propagation than OM. Finally, the additional rule significantly improves performance of SR against SM, especially the number of backtracks is lower by order of magnitude, which shows that the rule really facilitates propagation between the SPACING constraints.

Table 2. Number of solved instances / average time to solve in sec / average number of backtracks in thousands.

11 Conclusions

The global SPACING constraint is useful in modeling events that are distributed over time, like learning units scheduled over a study program or repeated patterns in music compositions. We have investigated theoretical properties of the constraint and shown that enforcing domain consistency (*DC*) is intractable even in very restricted cases. On the other hand we have identified two tractable restrictions and implemented efficient *DC* filtering algorithms for one of them. The algorithm takes $O(p^2k + p^{2.5})$ time down a branch of the search tree. We have also proposed an incomplete filtering algorithm for one of the intractable cases. We have experimentally evaluated performance of the algorithms on a music composition problem and demonstrated that our filtering algorithms outperform the state-of-the-art approach for solving this problem in both, speed and number of backtracks.
